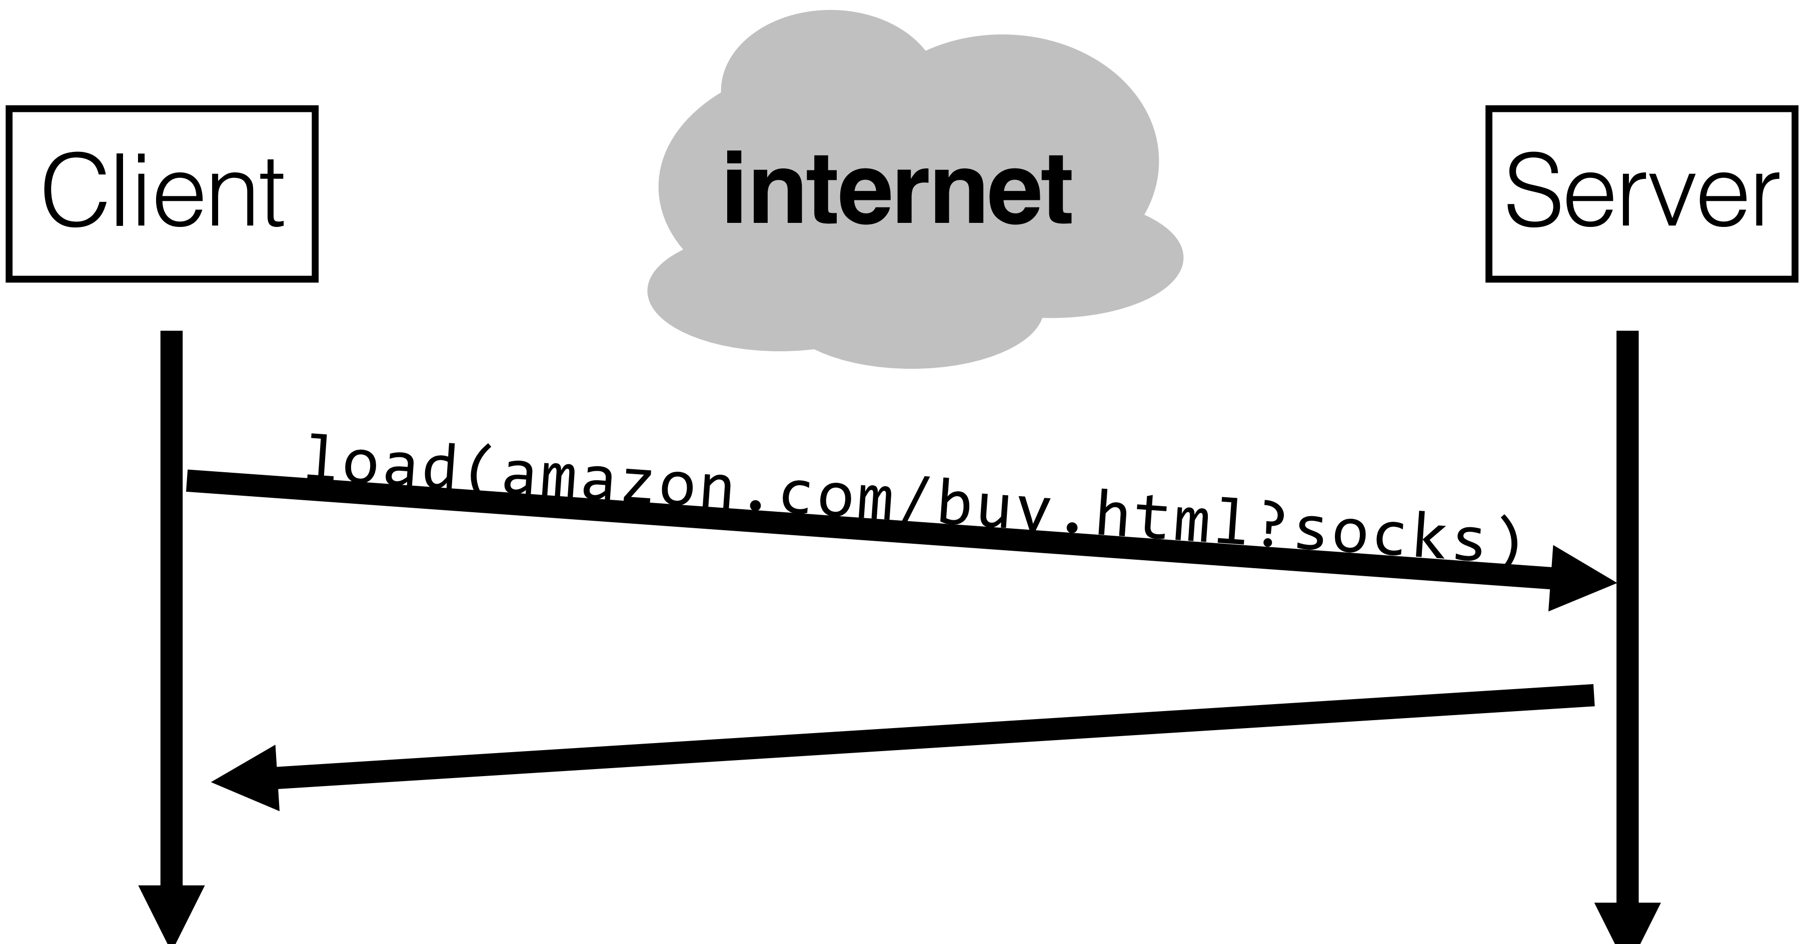
# 6.033 Spring 2018

## Lecture #3

- Operating systems
- Virtual memory
- OS abstractions

# Lingering Problem



what if we don't want our modules to be on entirely separate machines? how can we **enforce modularity on a single machine**?

# **operating systems** enforce modularity on a single machine

in order to enforce modularity + build an effective operating system

1. programs shouldn't be able to refer to (and corrupt) each others' **memory**

2. programs should be able to **communicate**

3. programs should be able to **share a CPU** without one program halting the progress of the others

# **operating systems** enforce modularity on a single machine using **virtualization**

in order to enforce modularity + build an effective operating system

1. programs shouldn't be able to refer to (and corrupt) each others' **memory** → virtualize **memory**
2. programs should be able to **communicate** → virtualize **communication links**
3. programs should be able to **share a CPU** without one program halting the progress of the others → virtualize **processors**

# **operating systems** enforce modularity on a single machine using **virtualization**

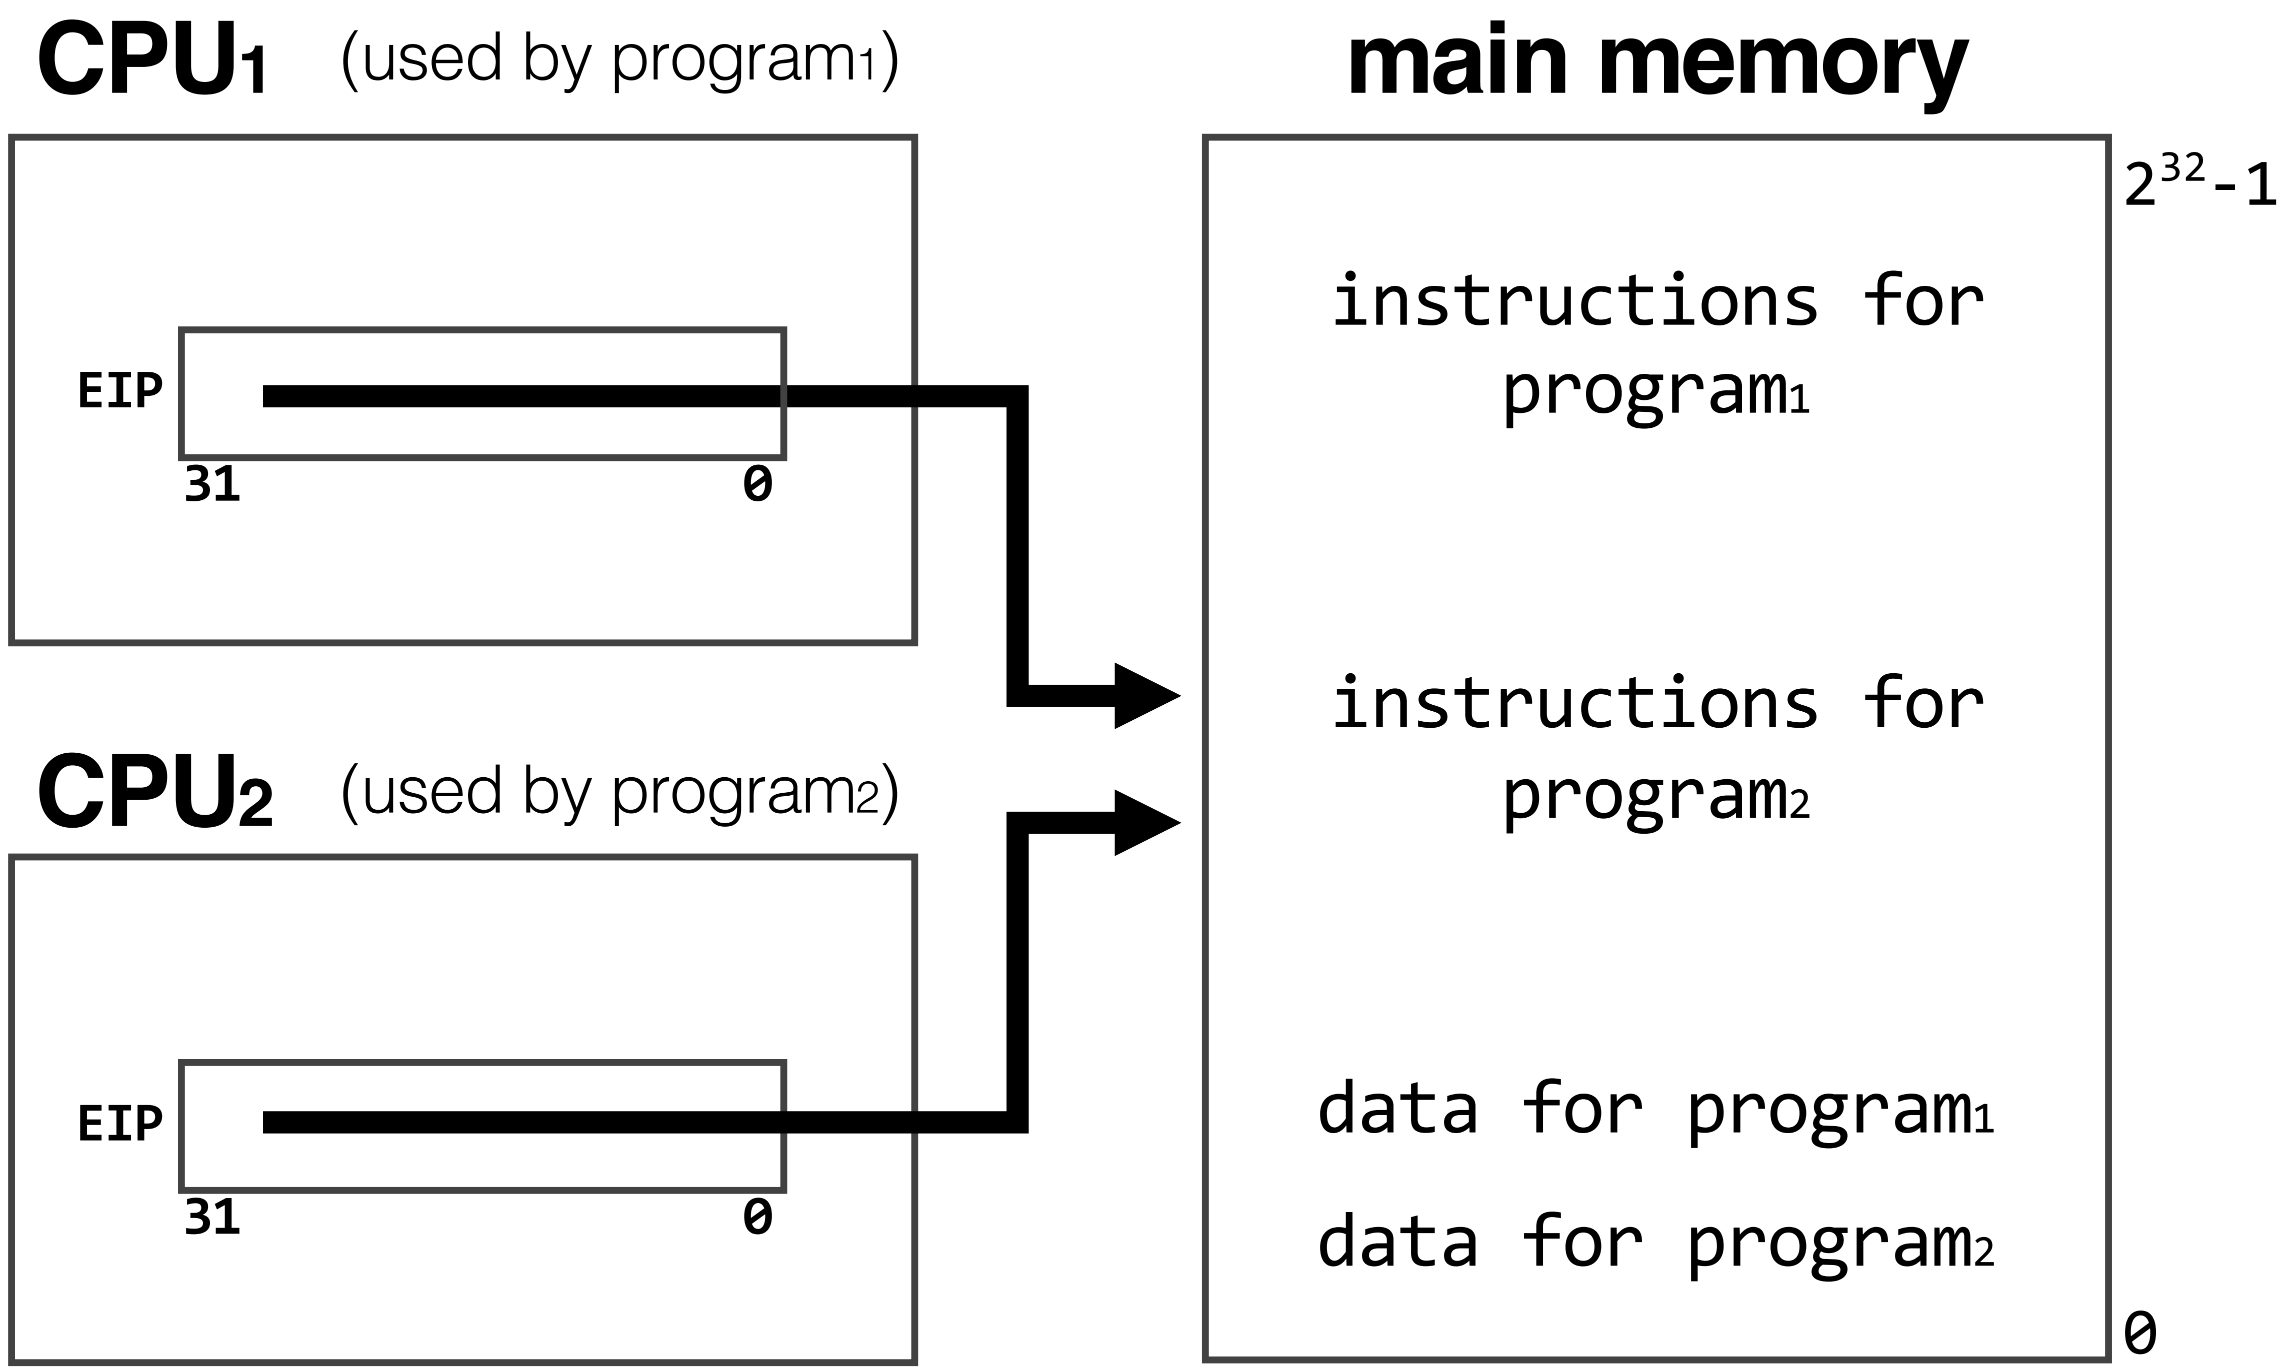
in order to enforce modularity + build an effective operating system

1. programs shouldn't be able to refer to (and corrupt) each others' **memory** → **virtual memory**
2. programs should be able to **communicate** → assume that they don't need to (for today)
3. programs should be able to **share a CPU** without one program halting the progress of the others → assume one program per CPU (for today)

**today's goal:** **virtualize memory** so that programs cannot refer to each others' memory

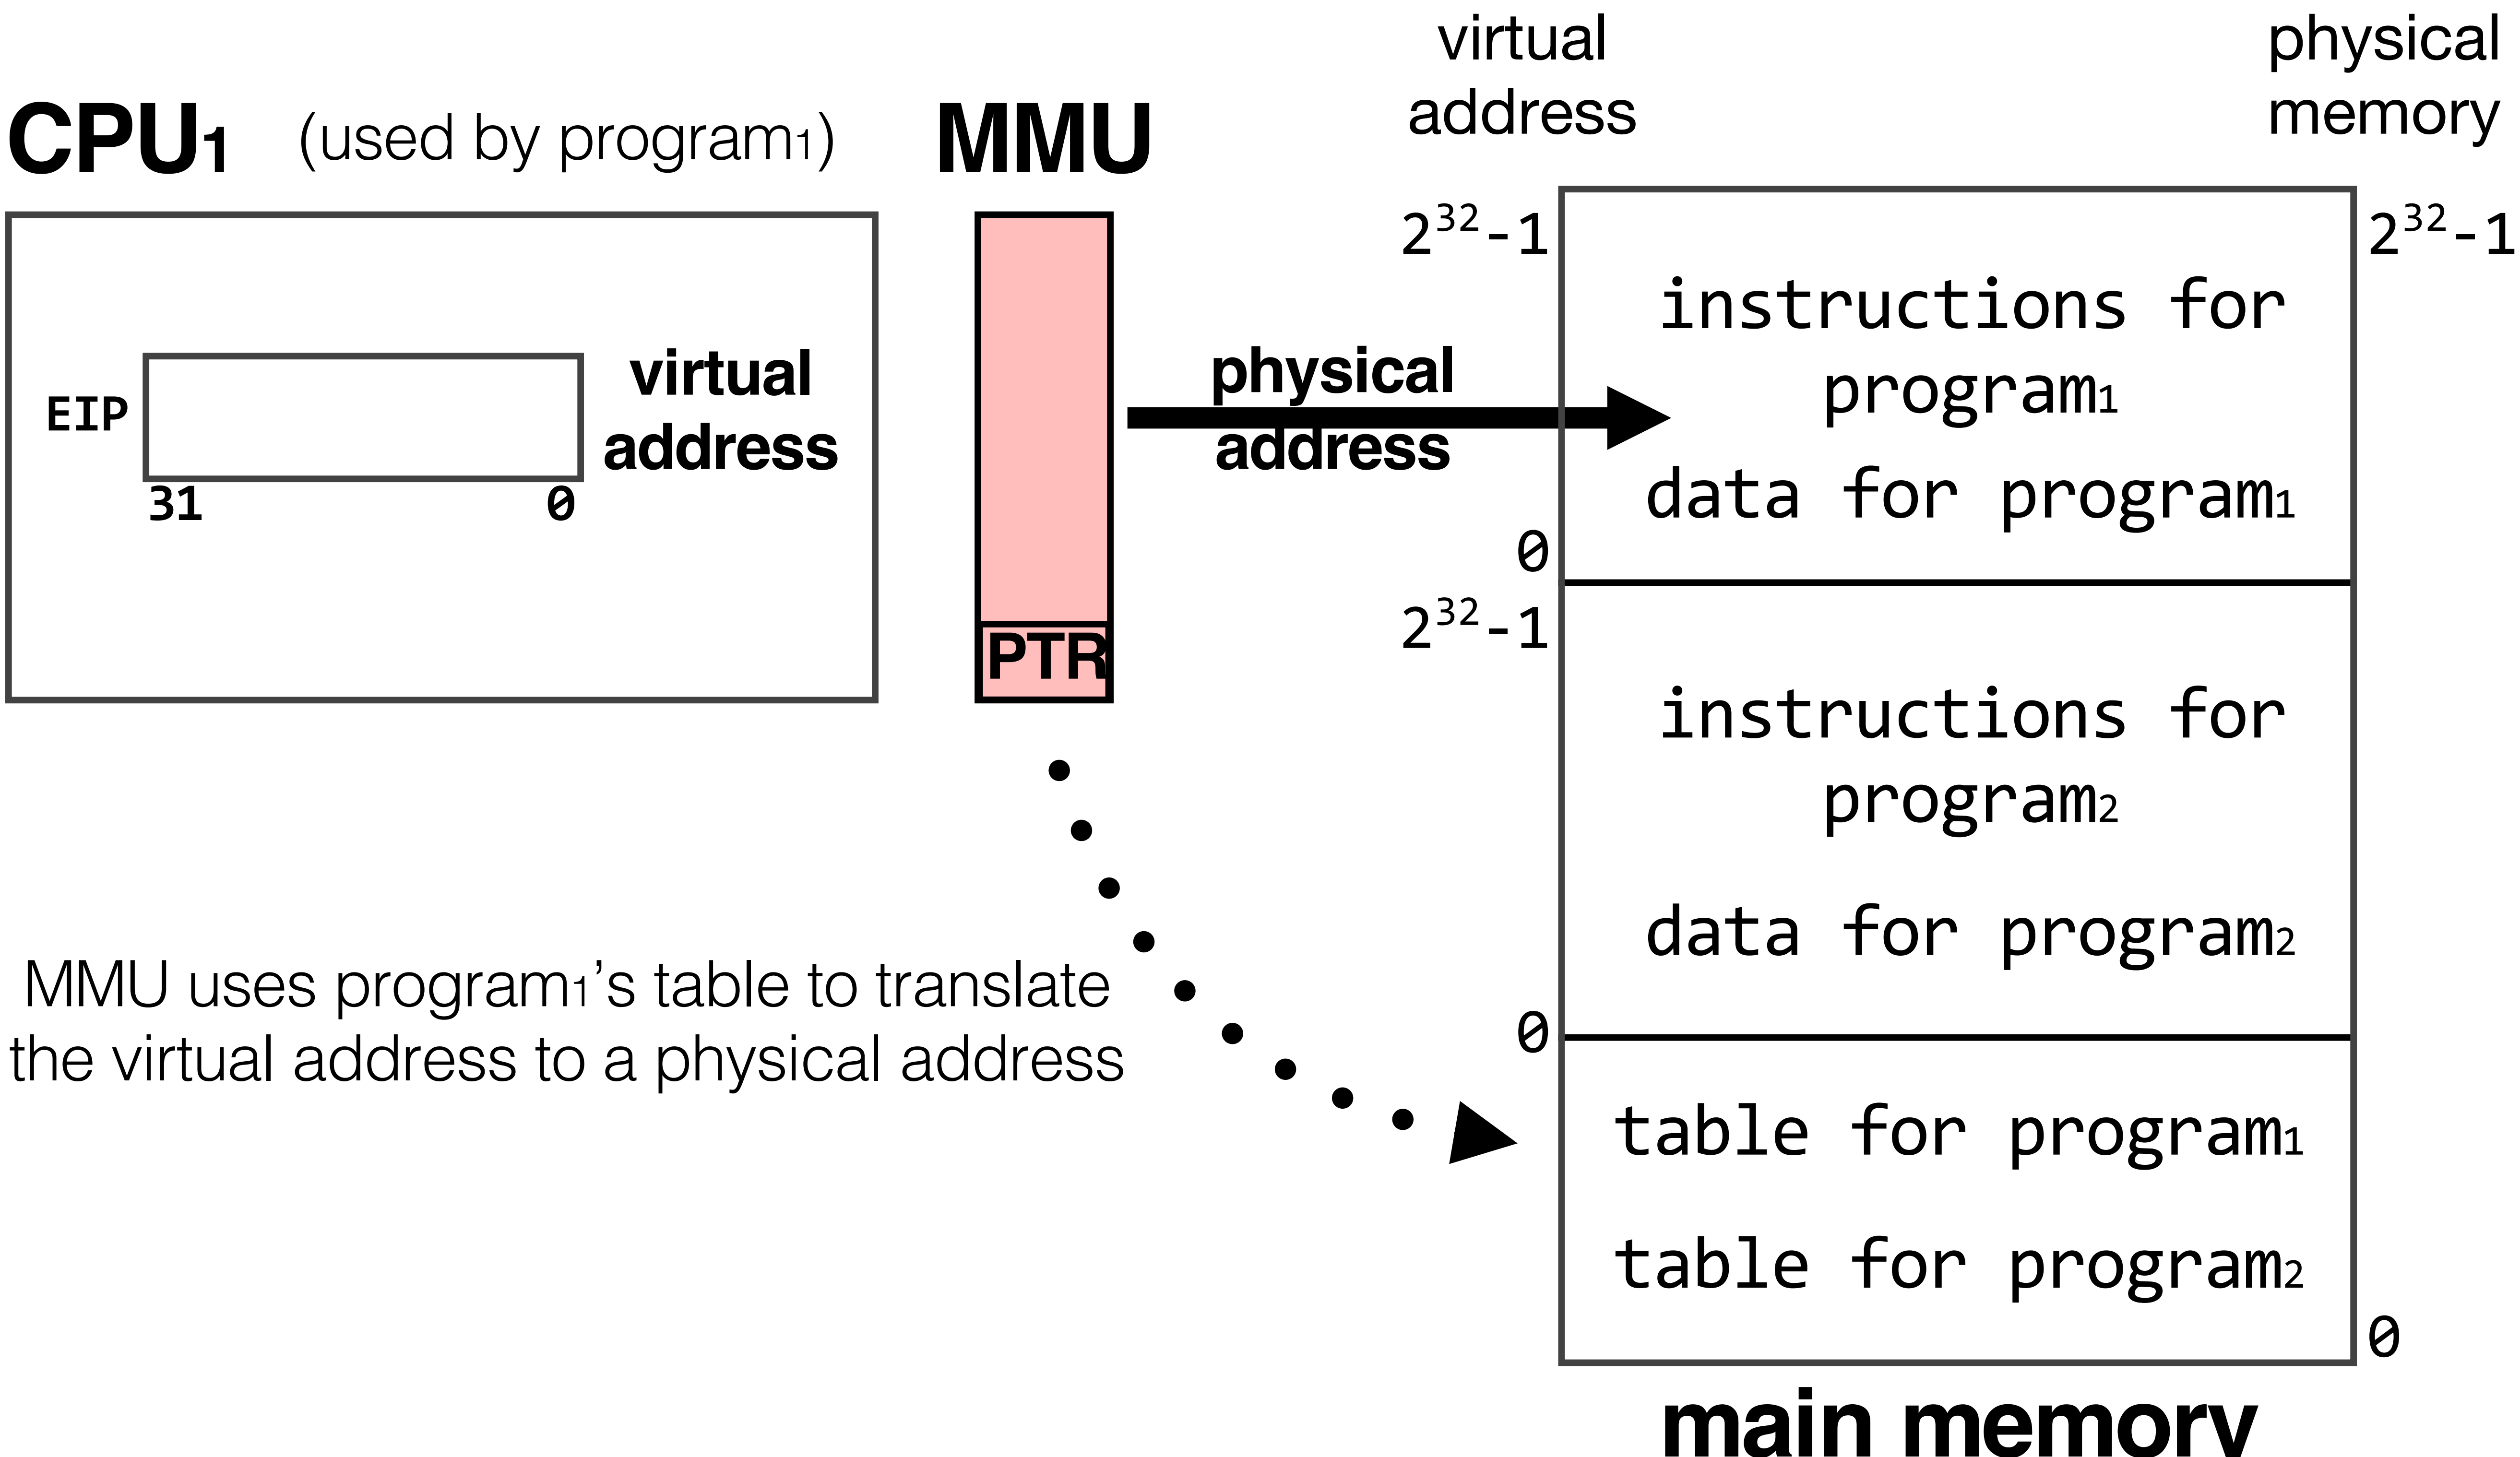
# how does a program use memory?

# Multiple Programs



**problem:** no boundaries

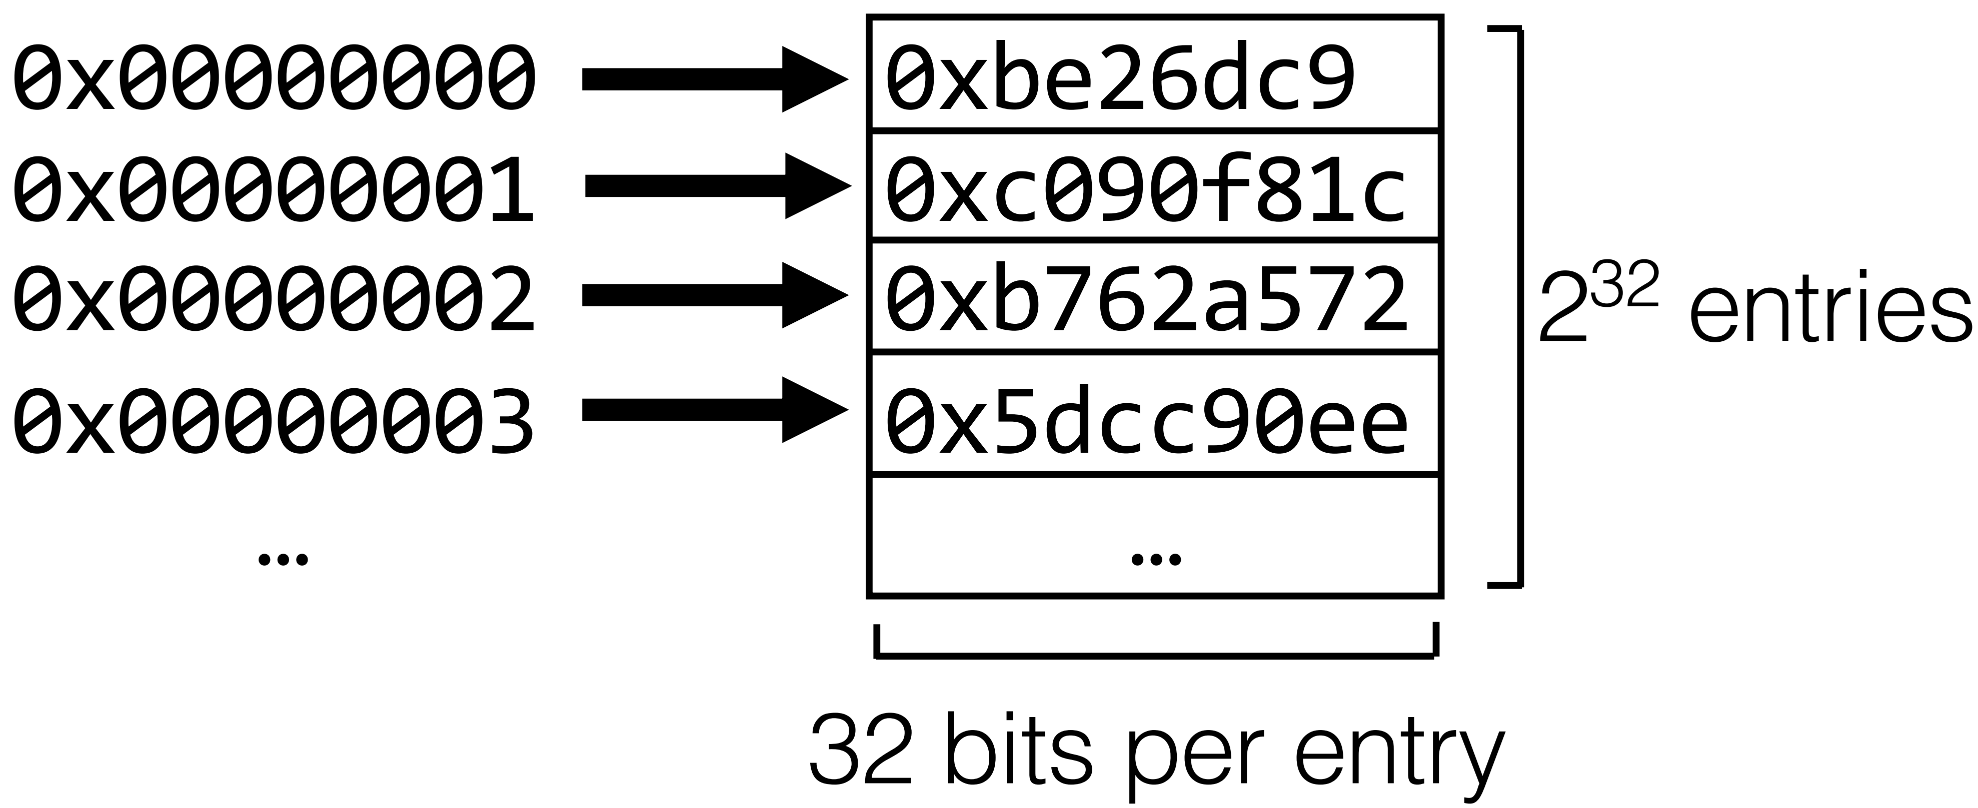
# Solution: Virtualize Memory



MMU uses program1's table to translate the virtual address to a physical address

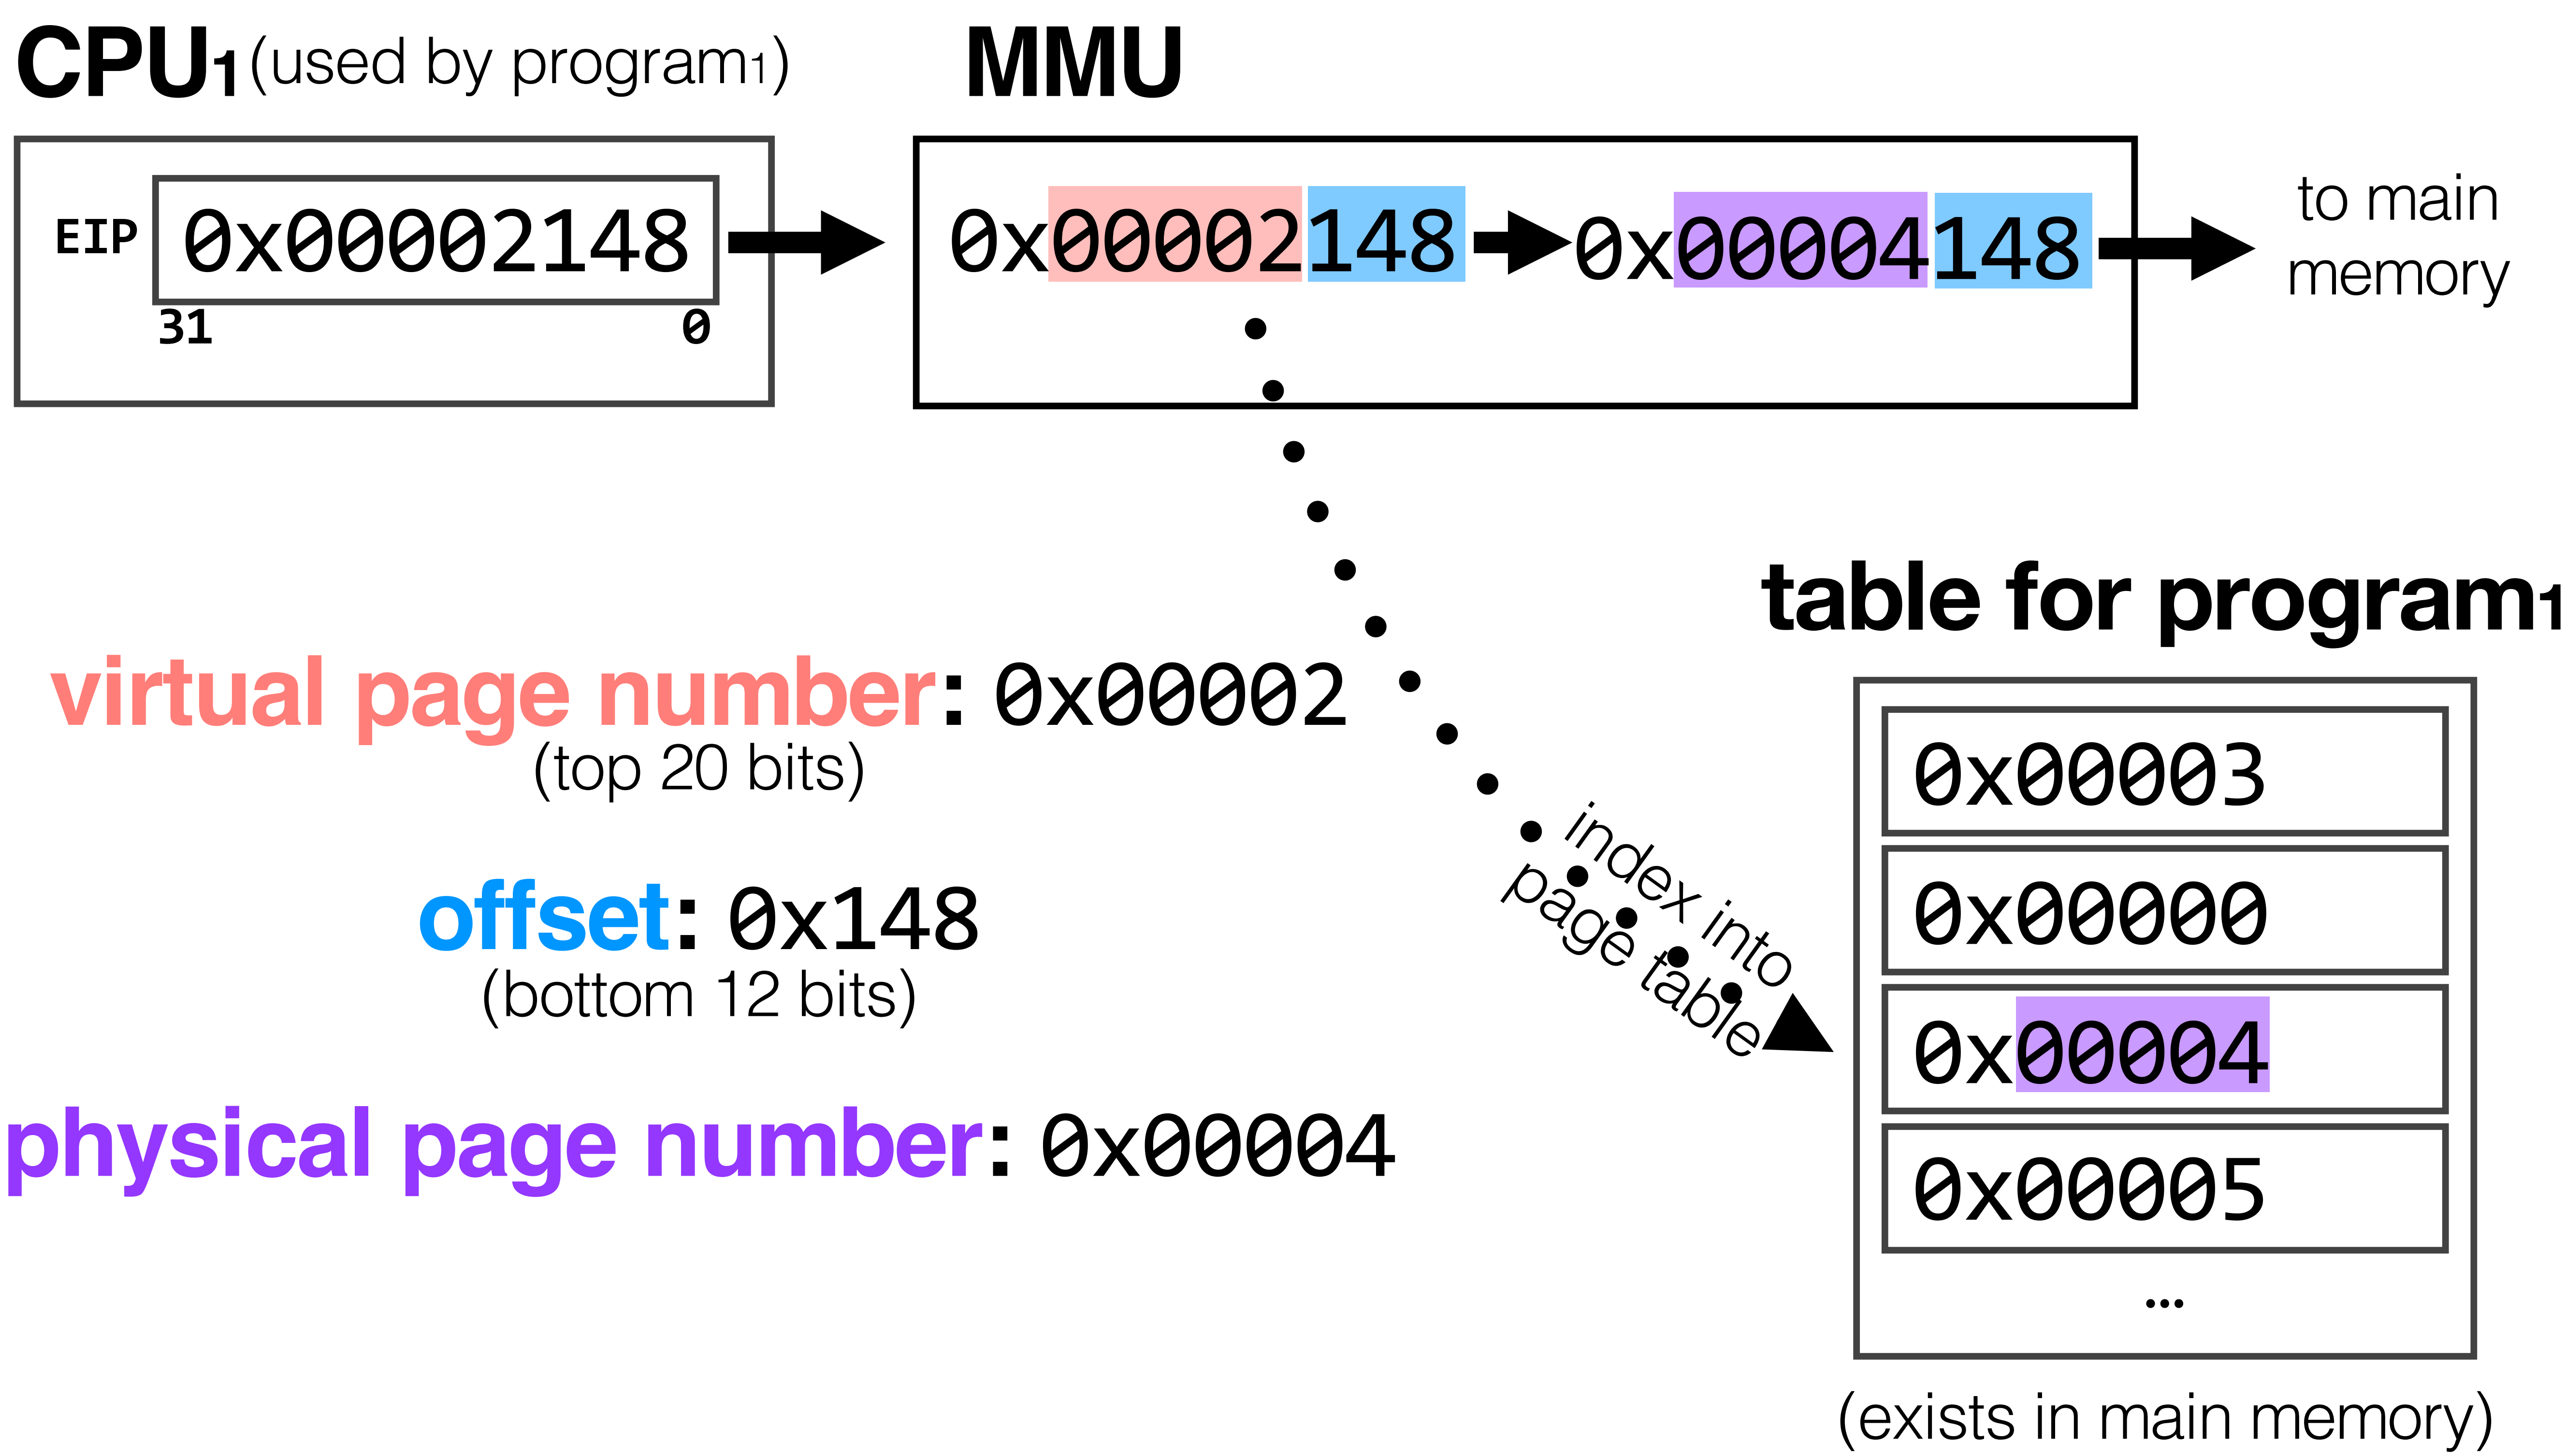
# Storing the Mapping

**naive method:** store every mapping; virtual address acts as an index into the table



= **16GB** to store the table

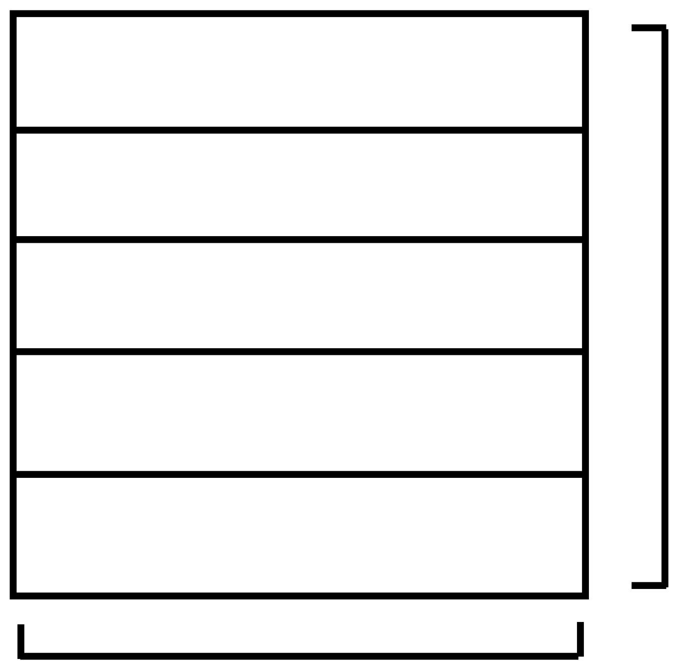
# Using Page Tables



# Storing the Mapping

**space-efficient mapping:** map to **pages** in memory

one page is (typically) $2^{12}$ bits of memory.



$2^{32-12} = 2^{20}$ entries

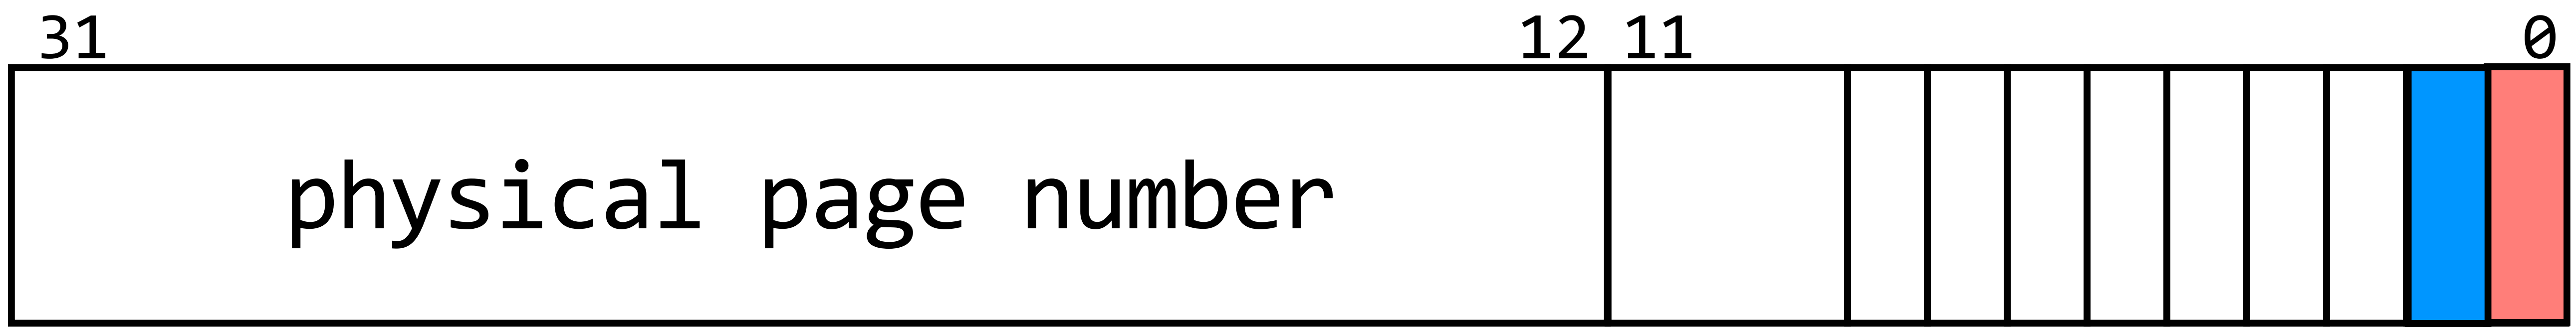
32 bits* per entry

= **4MB** to store the table

* you'll see why it's not 20 bits in a second

# Page Table Entries

page table entries are 32 bits because they contain a 20-bit physical page number and 12 bits of additional information



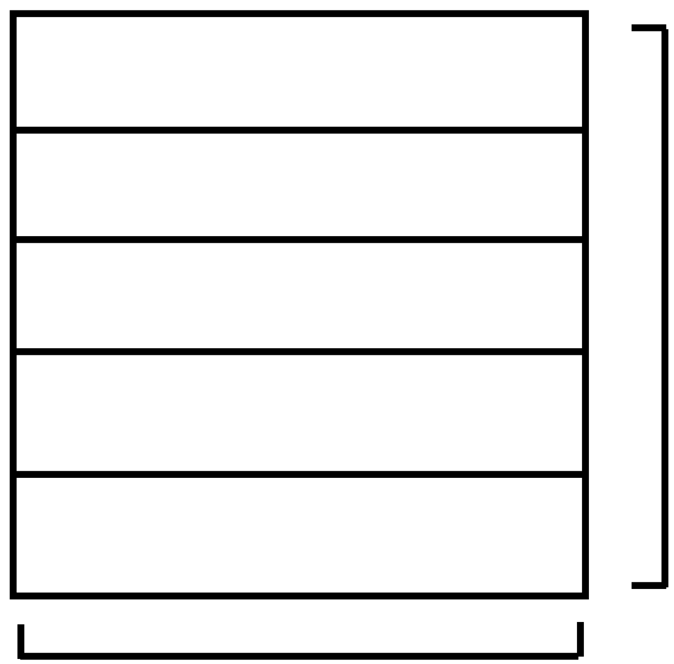
**present (P) bit:** is the page currently in DRAM?

**read/write (R/W) bit:** is the program allowed to write to this address?

# Storing the Mapping

**space-efficient mapping:** map to **pages** in memory

one page is (typically) $2^{\mathbf{12}}$ bits of memory.



$2^{32-\mathbf{12}} = 2^{20}$ entries

32 bits per entry

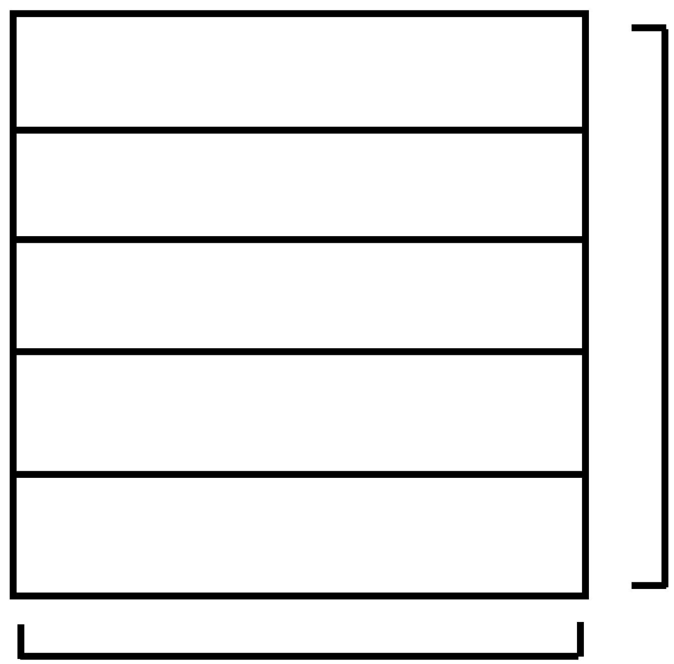
= **4MB** to store the table

**problem:** 4MB is still a fair amount of space

# Storing the Mapping

**space-efficient mapping:** map to **pages** in memory

one page is (typically) $2^{12}$ bits of memory.



$2^{32-12} = 2^{20}$ entries

32 bits per entry

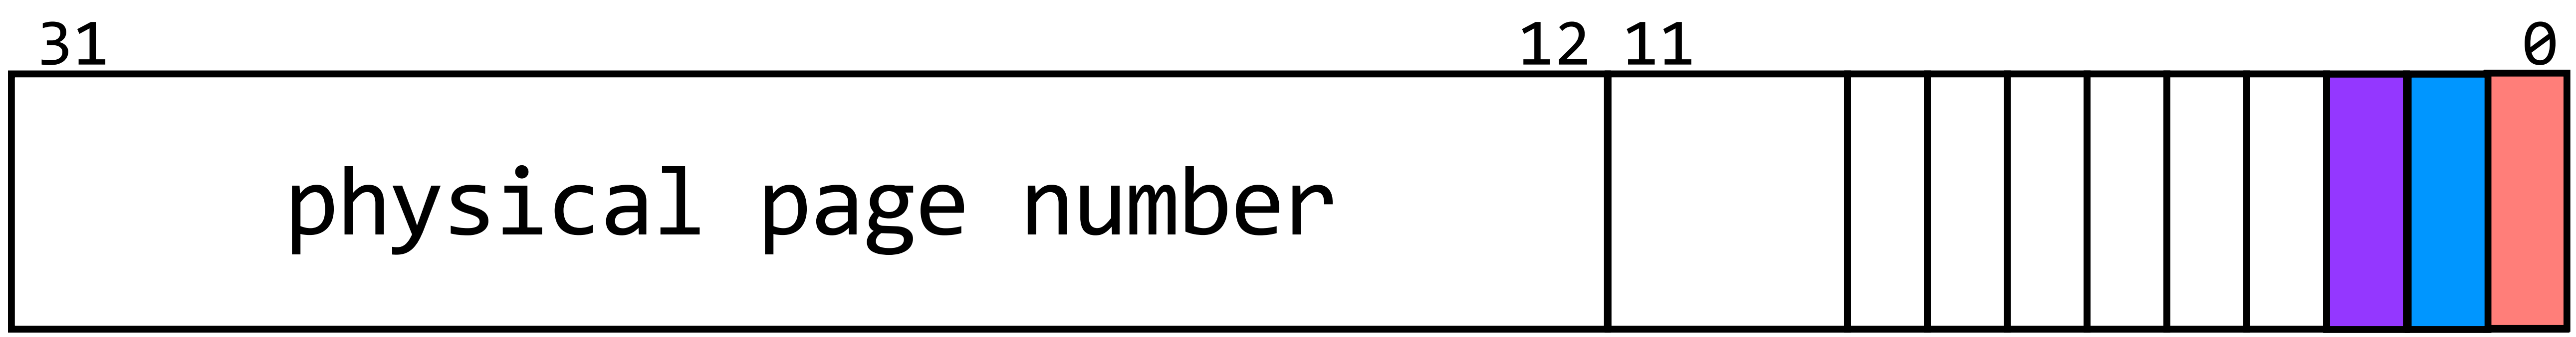
= **4MB** to store the table

**solution:** page the page table

**did we achieve our goal? is a program's memory protected from corruption by another program?**

# Page Table Entries

page table entries are 32 bits because they contain a 20-bit physical page number and 12 bits of additional information



**present (P) bit:** is the page currently in DRAM?

**read/write (R/W) bit:** is the program allowed to write to this address?

**user/supervisor (U/S) bit:** does the program have access to this address?

**kernel** manages **page faults** and other **interrupts**

**operating systems:** enforce modularity on a single machine via **virtualization**

**operating systems:** enforce modularity on a single machine via **virtualization** and **abstraction**

```c
#include <stdio.h>
#include <unistd.h>

void (*m)();

void f() {
  printf("child is running m = %p\n", m);
}

int main() {
  m = f;

  if (fork() == 0) {
    printf("child has started\n");
    int i;
    for (i = 0; i < 15; i++) {
      sleep(1);
      (*m)();
    }
  }

  else {
    printf("parent has started\n");
    sleep (5);
    printf("parent is running; let's write to m = %p\n", m);
    m = 0;
    printf("parent tries to invoke m = %p\n", m);
    (*m)();
    printf("parent is still alive\n");
  }
}
```

`m` is a pointer to a function that returns **`void`**

set `m` to point to `f`

Child: every second for 15 seconds, call `m`

Parent: overwrite `m` and then call it

- **Operating systems** enforce modularity on a single machine via **virtualization** and **abstraction**

- **Virtualizing memory** prevents programs from referring to (and corrupting) each other's memory. The **MMU** translates virtual addresses to physical addresses using **page tables**

- The OS presents **abstractions** for devices via system calls, which are implemented with interrupts. Using interrupts means the **kernel** directly accesses the devices, not the user
